

A Deep Graph Neural Network-Based Mechanism for Social Recommendations

Zhiwei Guo Dand Heng Wang

Abstract-Nowadays, the issue of information overload is gradually gaining exposure in the Internet of Things (IoT), calling for more research on recommender system in advance for industrial IoT scenarios. With the ever-increasing prevalence of various social networks, social recommendations (SoR) will certainly become an integral application that provides more feasibly personalized information service for future IoT users. However, almost all of the existing research managed to explore and quantify correlations between user preferences and social relationships, while neglecting the correlations among item features which could further influence the topologies of some social groups. To tackle with this challenge, in this article, a deep graph neural network-based social recommendation framework (GNN-SoR) is proposed for future IoTs. First, user and item feature spaces are abstracted as two graph networks and respectively encoded via the graph neural network method. Next, two encoded spaces are embedded into two latent factors of matrix factorization to complete missing rating values in a user-item rating matrix. Finally, a large amount of experiments are conducted on three real-world data sets to verify the efficiency and stability of the proposed GNN-

computers are deeply interacted. In recent years, the rapid development of the Internet of Things (IoT) technology contributes a lot to the realization of this vision. Predictably, IoT will become another cyberspace closely related to the daily life of people in the future, where colorful social, recreational, and working activities can be carried out. In contrast to the prevalence of future IoT, explosive increase in the amount of information will become an inevitable circumstances, possibly making IoT users sink into the ocean of information and without being able to find the information they require. To avoid information overload problem, it is of great significance to investigate recommender system (RS) in advance for industrial IoT scenarios. RS suggests suitable items for users according to their preference feedback, and is certainly a promising application in future IoT. In consideration of the ever-increasing popularity of various social networks, integration of social network into RS will provide IoT users more a suitably personalized information service. Thus, this article focuses on research of social recommendations (SoR) for future IoT users. Social networks are essentially a kind of graph network with two core components: users and the relationships among users. Thus, one universal scenario of SoR can be expressed as the inferring unknown preference feedback through information on social relationships. However, generating recommendations in social networks is never an easy task, because representation and quantification of various relationship features remain challenging.

To solve this problem, a considerable number of researchers have engaged in the investigation of SoR for a long period, producing a considerable number of related techniques [1]–[23]. Almost all of them managed to explore and quantify correlations between user preferences and social relationships. Obviously, users have a greater possibility to be affected by those who have stronger social relationships. Nevertheless, existing solutions only concentrated on modeling of user feature space, while neglecting item feature space. In fact, correlations also exist among item features, which will eventually impact the real preference features of social network users and internal topologies in social networks. Fig. 1 gives a typical example to demonstrate this view. Similar to the movie Saving Private Ryan, which has many attributes such as director, 1st actor, 2nd actor, etc., it is easy to see that there are relationships among all the attributes (e.g., Steven Spielberg ever cooperated with Tom Hanks). For many social groups, what really arouses their interest is not Steven Spielberg or Tom Hanks, but the combination of the two. Similarly for RS, in the scene of IoT, relationships among item features are expected to act as a more critical element.

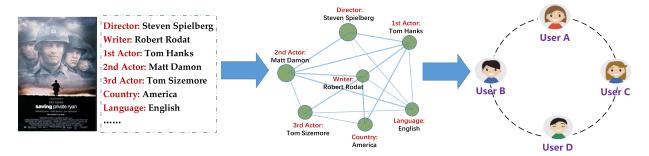

Fig. 1. Typical Example to Illustrate Relationships Among Item Attributes.

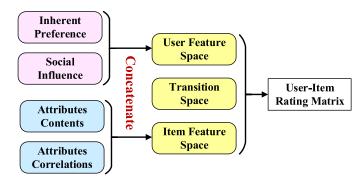

Fig. 2. Flowchart for Solution Thoughts of This Research.

To tackle the challenge, intuitively, feature space of SoR is supposed to be regarded as the synthesis of user feature and item feature (shown as Fig. 2). User feature is the concatenation of inherent preference and their social influence, which is universally studied by previous works. While item feature leverages concatenation of item attributes and their relationships, which is what this article distinguishes itself from existing research. Specifically, the user and item features are fundamentally two graph networks including entities and relations which can be well represented by the novel technique graph neural network. Thus, in this article, a deep graph neural network-based s ocial recommendation framework (GNN-SoR) is proposed for future IoT. First, user feature space and item feature space are abstracted as two graph networks and respectively encoded through graph neural network method. Next, the encoded two spaces are viewed as two latent factors in the process of matrix factorization which is formulated to predict unknown preference ratings. Finally, a large amount of experiments are conducted on three real-world data sets to evaluate efficiency and stability of the proposed GNN-SoR.

II. PROBLEM STATEMENT

Let $u_i (i=1,2,\ldots,n)$ be the set of n users and $v_j (j=1,2,\ldots,m)$ be the set of m items. It is assumed that user u_i may interact with item v_j through releasing preference rating r_{ij} , and that $\mathbf{R} = \{r_{ij}\} \in \mathbb{R}^{n \times m}$ denotes the user-item rating matrix. As it is unlikely that each user has interaction records with all the items, some elements of the initial rating matrix are likely to be empty and can be represented as $r_{ij} = 0$.

For user u_i , he can create or delete social relations with another user $u_k(k=1,2,\ldots,n;k\neq i)$ in the user set. Note that this paper just considers whether the social relations exist or not, regardless of strength degree. Thus, adjacency matrix of user-user relations is represented by $\mathcal{N}_{ik}(i,k=1,2,\ldots,n;i\neq k)$, in which \mathcal{N}_{ik} is binary and has two possible values 0 or 1. Among, $\mathcal{N}_{ik}=1$ denotes that user u_i has social relations with user u_k , and $\mathcal{N}_{ik}=0$ denotes no social relations.

For item v_j , its attributes are denoted as $a_{j\alpha}(\alpha=1,2,\ldots,z)$. It is assumed that adjacency matrix of attribute-attribute correlations of item v_j is represented as $\mathbf{A}=\mathcal{A}_j(\alpha,\beta)$ where $\alpha,\beta=1,2,\ldots,z$ and $\beta\neq\alpha$. Clearly, α and β are the indexes of attribute pairs. Similarly, elements of \mathbf{A} are binary of 0 or 1, where $\mathcal{A}_j(\alpha,\beta)=1$ denotes existence of correlations and $\mathcal{A}_j(\alpha,\beta)=0$ otherwise.

Given the above, the main goal of the SoR task is to predict unknown preference ratings in the rating matrix \mathbf{R} . The roadmap of the proposed GNN-SoR is illustrated in Fig. 3.

III. METHODOLOGY

This section describes detailed mathematical modeling process of the proposed GNN-SoR framework and contains three subsections: user feature modeling, item feature modeling and rating prediction.

A. User Feature Modeling

1) Inherent Preference: Inherent preference in this research refers to known preference features of users, and an m-dimensional inherent preference vector $p_i (i=1,2,\ldots,n)$ is supposed to be set up for each user u_i to represent his inherent preference. A typical case of p_i is illustrated as $p_i = [r_{i1}, r_{i2}, \ldots, r_{im}]$, where m is the number of items. The purpose of inherent preference encoding is to transform the p_i into another encoded vector h_i^I called inherent preference factor, which is expressed as:

$$h_i^I = \sigma_1 \left\{ \mathbf{W}_1 \cdot f_1 \left(\mathbf{p}_i \right) + \mathbf{b}_1 \right\} \tag{1}$$

where $\sigma_1(\cdot)$ is non-linear activation function ReLU [24], $f_1(p_i)$ is a function that automatically extracts abstract feature expression of p_i by mapping it into a novel feature value. p_i can be transformed into another vector p'_i which comprises multiple concatenations of three elements of p_i in turn. The p'_i can be

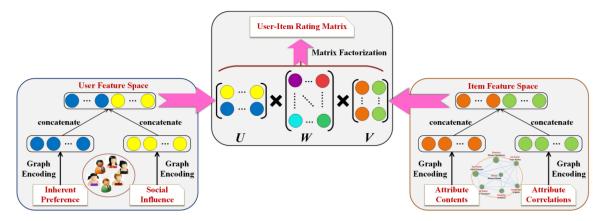

Fig. 3. Roadmap Architecture of the GNN-SoR.

illustrated as the following vector format:

$$[(r_{i1}, r_{i2}, r_{i3}), (r_{i2}, r_{i3}, r_{i4}), \dots, (r_{i m-2}, r_{i m-1}, r_{im})] \quad (2)$$

where each concatenation in p'_i is its one element. Let $p'_{i\xi}(\xi = 1, 2, ..., \psi)$ denote all the elements in p'_i . Weighted mean operator is utilized to formulate $f_1(p_i)$ as:

$$f_{1}\left(\boldsymbol{p}_{i}\right) = \frac{1}{\psi} \sum_{\xi=1}^{\psi} a_{i} \cdot \left(\boldsymbol{p'}_{i\xi}\right)^{T}$$

$$(3)$$

where a_i is 3-D vector. Equation. (1) can be rewritten as

$$h_i^I = \sigma_1 \left\{ \boldsymbol{W}_1 \left[\frac{1}{\psi} \sum_{\xi=1}^{\psi} \boldsymbol{a}_i \cdot \left(\boldsymbol{p'}_{i\xi} \right)^T \right] + b_1 \right\}$$
(4)

where W_1 and b_1 are parameter vectors.

2) Social Influence: In this part, an n-1-dimensional vector $s_i (i=1,2,\ldots,n)$ is set up for user u_i to represent their social influence feature, where n-1 is the number of resting users except u_i . A typical case of s_i is illustrated as $s_i = [\mathcal{N}_{i1}, \mathcal{N}_{i2}, \ldots, \mathcal{N}_{i \ n-1}]$, where value of \mathcal{N}_{ik} is 0 or 1. The goal of social influence encoding is to transform the s_i into one another encoded vector h_i^S called social influence factor, which is expressed as

$$\boldsymbol{h}_{i}^{S} = \sigma_{1} \left[\boldsymbol{W}_{2} \cdot f_{2} \left(\boldsymbol{s}_{i} \right) + \boldsymbol{b}_{2} \right] \tag{5}$$

where $f_2(s_i)$ is another function that automatically extracts abstract feature expression of s_i . Mean operator is introduced to construct mapping function as

$$f_2(\mathbf{s}_i) = \mathbf{c}_i \cdot (\mathbf{s}_i)^T \tag{6}$$

where c_i is the weight vector for feature transition demonstrated as

$$\mathbf{c}_i = \boldsymbol{\omega}_1^T \cdot \sigma_1 \left(\boldsymbol{\omega}_2^T \cdot \boldsymbol{c}_i' + \tau_2 \right) + \tau_1 \tag{7}$$

where c'_i is latent hidden variable of user u_i , and ω_1^T , ω_2^T , τ_1 and τ_2 are model parameters. Eq. (5) can be rewritten as

$$m{h}_i^S = \sigma_1 \left\{ m{W}_2 \left[m{\omega}_1^T \cdot \ \sigma \left(m{\omega}_2^T \cdot m{c'}_i + au_2 \right) + au_1 \right] \cdot (m{s}_i)^T + m{b}_2
ight\}$$
(8)

where W_2 and b_2 are parameter vectors. Note that introduction of two trade-off parameters is to improve generalization capability of the item feature subspace.

3) Concatenation: The combination process here is implemented with the aid of multi-layer perception, where the first hidden layer vector is concatenation of h_i^I and h_i^S . The process is a ζ -round iterative process and illustrated as the following formulas:

$$\boldsymbol{U}_{i}^{(0)} = \left[\boldsymbol{h}_{i}^{I} \oplus \boldsymbol{h}_{i}^{S}\right] \tag{9}$$

$$U_i^{(1)} = \sigma_1 \left[W_3 \cdot U_i^{(0)} + b_3 \right]$$
 (10)

. . .

$$\boldsymbol{U}_{i}^{(\zeta)} = \sigma_{1} \left[\boldsymbol{W}_{3} \cdot \boldsymbol{U}_{i}^{(\zeta-1)} + \boldsymbol{b}_{3} \right]$$
 (11)

where W_3 and b_3 are parameter vectors, and contents in the upper right corner bracket of U_i is the number of iterative rounds.

B. Item Feature Modeling

1) Attribute Contents: As the attribute contents of items are usually not feasible for vectorized or convolutional computations, especially since some of them are textual data, it is expected to map them into vectorized numerical data. Attribute contents of items can be roughly divided into two types: structured attributes and unstructured attributes.

Taking the movie *Saving Private Ryan* in Fig. 1 as an example, the listed attributes (Director, 1st Actor, Language, Country, etc.) in Fig. 1 are all structured attributes, because their contents are a fixed range of options (specific names of persons). Contents of categorical attributes are encoded into feature vector via one-hot encoding demonstrated as Table I.

As for other possible attributes such as textual reviews, the Twitter-LDA algorithm [25] is utilized to extract topics. Twitter-LDA is generally applied to short text classification, and is able to assign each paragraph of text a latent topic from a set of latent topics. The total number of latent topics can be determined manually or adaptively. All the textual contents associated with

TABLE I
EXAMPLE FOR STRUCTURED ATTRIBUTES ENCODING

Attributes	Encoded Formats
Director	[1,0,,0]
1st Actor	$[0,1,\cdots,0]$
Language	$[0,0,\cdots,1]$
Country	$[0,1,\cdots,0]$

one item are regarded as a whole for text classification, regardless of differing length. Mapping the result of textual data is the classification results that are also format of one-hot encoding.

Due to the possibility that dimensions of different attributes are not the same, attribute with the most dimensions will be selected as uniformity. Therefore, zeros are added to corresponding encoding results of other attributes to unify dimension of all the attributes. Dimension number of attributes is denoted as D, thus content factor of attributes for item v_j can be represented as

$$C_j = [c(a_{j1}), c(a_{j2}), \dots, c(a_{jz})]$$
 (12)

where z is the number of attributes for item v_j and $c(a_{j1}) \in \mathbb{R}^D$. 2) Attribute Correlations: For attribute $a_{j\alpha}$ of item v_j , it is supposed to aggregate correlation information from other attributes and make it encoded. The encoding vector of attribute correlations for item v_j is expressed as

$$E_{j} = \sum_{\alpha=1}^{z} \sum_{\beta=1 \atop \beta \neq \alpha}^{z} \mathcal{A}_{j} (\beta, \alpha) \cdot \mathcal{M}$$
 (13)

where \mathcal{M} is the transformation function, and $\mathcal{A}_j(\beta, \alpha)$ is the weight of directed correlation edge from attribute $a_{j\beta}$ to attribute $a_{j\alpha}$. Specifically, $\mathcal{A}_j(\alpha, \beta)$ is inferred as

$$w_{j}(\alpha, \beta) = \frac{\operatorname{Count}(a_{j\alpha} \cap a_{j\beta}) / \operatorname{Count}(a_{j\beta})}{\sum_{\gamma} \operatorname{Count}(a_{j\alpha} \cap a_{j\gamma}) / \operatorname{Count}(a_{j\gamma})}$$
(14)

$$\mathcal{A}_{j}(\alpha,\beta) = \begin{cases} w_{j}(\alpha,\beta), & \text{if } \alpha \neq \beta \\ 0, & \text{else} \end{cases}$$
 (15)

where $\operatorname{Count}(a_{j\alpha} \cap a_{j\beta})$ is the co-occurrence frequency of attribute $a_{j\alpha}$ and attribute $a_{j\beta}$, $\operatorname{Count}(a_{j\beta})$ is occurrence frequency of attribute $a_{j\beta}$, and γ is another index number for attributes of item v_j ($\gamma \neq \alpha, \beta$). As for \mathcal{M} , each correlation edge assigned a unique transformation weight will lead to complex computation and redundant time consumption. Following [26], each attribute $a_{j\alpha}$ is assigned an input matrix $\mathcal{M}_{j\alpha}^{(\mathrm{IN})}$ and an output matrix $\mathcal{M}_{j\alpha}^{(\mathrm{OUT})}$. As for a directed correlation edge from attribute $a_{j\alpha}$ to attribute $a_{j\beta}$, state information is transformed from $\mathcal{M}_{j\alpha}^{(\mathrm{OUT})}$ to $\mathcal{M}_{j\beta}^{(\mathrm{IN})}$, which is expressed as:

$$\mathcal{M}_{j(\alpha \to \beta)} = \mathcal{M}_{j\alpha}^{(\text{OUT})} \cdot \mathcal{M}_{j\beta}^{(\text{IN})}$$
 (16)

Similarly, as for a directed correlation edge from attribute $a_{j\beta}$ to attribute $a_{j\alpha}$, state information is calculated as:

$$\mathcal{M}_{j(\beta \to \alpha)} = \mathcal{M}_{j\beta}^{(\text{OUT})} \cdot \mathcal{M}_{j\alpha}^{(\text{IN})}$$
 (17)

Thus, (13) is rewritten as:

$$\boldsymbol{E}_{j} = \sum_{\alpha=1}^{z} \sum_{\beta=1 \atop \beta \neq \alpha}^{z} \mathcal{A}_{j} (\beta, \alpha) \cdot \mathcal{M}_{j\beta}^{(\text{OUT})} \cdot \mathcal{M}_{j\alpha}^{(\text{IN})} + \boldsymbol{b}_{E}$$
 (18)

where b_E is bias vector.

3) Concatenation: For item v_j , z attributes are viewed as nodes and correlations among attributes are viewed as edges in a graph structure. In order to reduce computational complexity, here we aggregate attribute correlations for each attribute into vector E_j that is regarded as edges in the graph. Given graph structure $\mathcal{G}(C_j, E_j)$, item feature space is constructed through updating factors of attribute contents and attribute correlations. Let $C_{j\alpha}$ denote α -th element in C_j and C_j denote the α -th element in C_j . Updating process of attribute contents factor C_j is shown as:

$$C_{j\alpha}^{(t)} = \sigma_2 \left[C_{j\alpha}^{(t-1)} + \sum_{\alpha=1}^{z} \sum_{\substack{\beta=1\\\beta \neq \alpha}}^{z} \boldsymbol{h}_j^{(t-1)} \right]$$
 (19)

where $\sigma_2(\cdot)$ is the sigmoid function expressed as:

$$\sigma_2(x) = \frac{1}{1 + e^{-x}}$$
 (20)

 $h_j^{(t-1)}$ is hidden neighborhood vector at t-1-th iteration with respect to all attribute pairs, and can be computed with consideration of elements in vector E_j :

$$\boldsymbol{h}_{j}^{(t)} = \sigma_{1} \left[\boldsymbol{W}_{4} \begin{bmatrix} C_{j\beta}^{(t)} \\ E_{j\alpha}^{(t)} \end{bmatrix} + \boldsymbol{b}_{4} \right]$$
 (21)

where W_4 and b_4 are parameter vectors. The above iterative process can be also used to update $E_{j\alpha}^{(t)}$ as following formulas:

$$E_{j\alpha}^{(t+1)} = \sigma_2 \left[E_{j\alpha}^{(t)} + E_{j\alpha}^{(t)} \right]$$
 (22)

$$E'_{j\alpha}^{(t+1)} = \sigma_1 \left[\boldsymbol{W}_5 \left(C_{j\alpha}^{(t)} + C_{j\beta}^{(t)} \right) + \boldsymbol{b}_5 \right]$$
 (23)

where W_5 and b_5 are parameter vectors. Finally, the item feature space can be obtained:

$$\boldsymbol{V}_{j} = C_{j\alpha}^{(t)} \tag{24}$$

And V_i is a $z \times m$ -dimensional matrix.

C. Rating Prediction

Then, missing rating values in user-item matrix can be completed through dot product of those two latent matrices. Due to $U_i \in \mathbb{R}^{n \times n}$ and $V_j \in \mathbb{R}^{z \times m}$, dot product operations cannot be conducted between them. Therefore, a transition matrix $W_{UV} \in \mathbb{R}^{n \times z}$ is defined to be located between the two matrices to match their dimensions. The rating prediction process can be expressed as

$$\hat{r}_{ij} = \boldsymbol{U}_i \cdot \boldsymbol{W}_{UV} \cdot \boldsymbol{V}_j \tag{25}$$

Conventionally, matrix factorization method appropriates missing rating values by solving the following optimization problem:

$$\min_{U_i, W_{UV}, V_j} \frac{1}{2} (\hat{r}_{ij} - r_{ij})^2 \tag{26}$$

where r_{ij} is real observed rating values. To avoid overfitting, it is supposed to introduce regularization terms related to U_i , W_{UV} , and V_j . U_i is concatenation of h_i^I and h_i^S , and V_j is concatenation of C_j and E_j . Thus, (26) can be rewritten as

$$\min_{U_{i},W_{UV},V_{j}} \frac{1}{2} \|\hat{r}_{ij} - r_{ij}\|_{F}^{2} + \frac{\lambda_{1}}{2} \left(\|\boldsymbol{h}_{i}^{I}\|_{F}^{2} + \|\boldsymbol{h}_{i}^{S}\|_{F}^{2} \right) + \frac{\lambda_{2}}{2} \left(\|\boldsymbol{C}_{j}\|_{F}^{2} + \|\boldsymbol{E}_{j}\|_{F}^{2} \right) + \frac{\lambda_{3}}{2} \|\boldsymbol{W}_{UV}\|_{F}^{2} \tag{27}$$

where λ_1 , λ_2 , and λ_3 are regularization parameters satisfying $\lambda_1, \lambda_2, \lambda_3 > 0$, and $\|\cdot\|_F^2$ is the Frobenius norm [27].

Stochastic gradient descent (SGD) is utilized to solve the optimization problem. SGD seeks out the minimum of the objective function through calculating partial derivatives of parameters and updates them iteratively to reduce empirical errors. Let $\,L$ denote component of objective function, partial derivatives are calculated as the following formulas:

$$\frac{\partial L}{\partial \boldsymbol{h}_{i}^{I}} = (\hat{r}_{ij} - r_{ij}) \frac{\partial \hat{r}_{ij}}{\partial \boldsymbol{h}_{i}^{I}} + \lambda_{1} \boldsymbol{h}_{i}^{I}$$
(28)

$$\frac{\partial L}{\partial \boldsymbol{h}_{i}^{S}} = (\hat{r}_{ij} - r_{ij}) \frac{\partial \hat{r}_{ij}}{\partial \boldsymbol{h}_{i}^{S}} + \lambda_{1} \boldsymbol{h}_{i}^{S}$$
(29)

$$\frac{\partial L}{\partial \boldsymbol{C}_{j}} = (\hat{r}_{ij} - r_{ij}) \frac{\partial \hat{r}_{ij}}{\partial \boldsymbol{C}_{j}} + \lambda_{2} \left(\boldsymbol{C}_{j} + E_{j\alpha} \frac{\partial \boldsymbol{E}_{j}}{\partial \boldsymbol{C}_{j}} \right)$$
(30)

$$\frac{\partial L}{\partial \mathbf{E}_{j}} = (\hat{r}_{ij} - r_{ij}) \frac{\partial \hat{r}_{ij}}{\partial \mathbf{E}_{j}} + \lambda_{2} \left(\mathbf{E}_{j} + \mathbf{C}_{j} \frac{\partial \mathbf{C}_{j}}{\partial \mathbf{E}_{j}} \right)$$
(31)

$$\frac{\partial L}{\partial \mathbf{W}_{UV}} = (\hat{r}_{ij} - r_{ij}) \frac{\partial \hat{r}_{ij}}{\partial \mathbf{W}_{UV}} + \lambda_3 \mathbf{W}_{UV}$$
(32)

Then, the computed partial derivatives are regarded as search directions at each iterative round to search for optimal solutions until convergence.

IV. EXPERIMENTS AND ANALYSIS

A. Data Sets

Data sets utilized in this research are three classical real-world data sets that are common in the field of SoR: *Epinions* [28], *Yelp* [29], *Flixster* [30]. We present descriptions of them and necessary preprocessing steps in this subsection.

Epinions—It was collected by Paolo Messa et al. from famous online shopping website epinions¹ through Internet crawlers in 2003. In this website, users are allowed to publish preference ratings towards items with an integer ranging from 1 to 5, and to set up trust relationships with others to facilitate making decisions. We filter out ratings with values less than four, and remove users releasing less than 5 ratings and items with no more than 5 ratings. As the initial Epinions contains no information of attribute contents and correlations, we crawl metadata (product attributes) from famous shopping website

TABLE II
STATISTICS OF POSTPROCESSED DATA SETS

Dataset	Epinions	Yelp	Flixster
Number of Users	19503	25040	21058
Number of Items	25216	13682	20867
Number of Ratings	435671	260374	905772
Number of Social Links	402218	220197	313870
Number of Attributes in Each Item	10	10	10
Number of Attribute Correlations	235276	112341	199345
Rating Density	0.089%	0.076%	0.206%
Social Density	0.063%	0.035%	0.071%

Amazon² according to the product information in Epinions. Then, correlation information of crawled attributes is quantified by searching co-occurrence records of attribute pairs. And the attribute correlation is represented as binary value of 0 or 1, where 1 denotes the existence of correlation and 0 otherwise.

Yelp—Yelp,³ a famous business review website in San Francisco, the United States, was founded in 2004. It this website, users can rate merchants, submit comments, exchange shopping experience, etc. The Yelp data set was collected and published by Yelp official, in order to call for innovative data mining methods for commercial development. The data set contains information about users and merchants, preference ratings of users towards merchants, and reviews of users on merchants, etc. Among, merchants in the data set are regarded as items, and correlations of attribute pairs can be extracted from information of merchants. We firstly select data just with category of restaurants for evaluation as total amount of data is too large, and then filter out users whose rating records is less than three. Besides, social relationships cannot be observed directly in Yelp data set, users commonly reviewing one same item are viewed as being socially related to each other.

Flixster—Flixster⁴ is an online social website concerning movies where users can share preference ratings and meet others. The Flixster data set was collected by researchers from Arizona State University. It contains rich preference ratings of users towards items and social relationships among users. As for attributes of items, we crawl metadata from a famous online movie database named IMDb⁵ and extract correlations of attributes. Note that ratings in Flixster are real values from 0.5 to 5.0 with step 0.5, so we further transform the nonintegral rating values into integers.

The statistics of post-processed data sets are listed in Table II.

B. Experimental Settings

To evaluate the efficiency of the proposed GNN-SoR framework, we employ three widely used evaluation metrics in RS: RMSE, MAE, and NDCG. RMSE refers to root mean squared error, and is a usual index to measure diverse degree between real

values and prediction values. MAE refers to mean absolute error, and is defined as mean value of absolute error. As for RMSE and MAE, a lower value denotes better performance. NDCG refers to normalized discounted cumulative gain, and measures the quality of ranking through discounted importance based on positions. A higher value of NDCG denotes better performance. Detailed definitions of these metrics are demonstrated in [31] and [32]. And four classical methods concerning SoR are selected as baselines: TrustMF [6], SocialMF [8], TrustSVD [14], and AutoRec [33]. Their detailed descriptions are illustrated in corresponding literatures.

The proposed GNN-SoR is implemented with the aid of TensorFlow, a well-known programming toolkit for deep learning. Number of iterative rounds ψ and ζ respectively in (3) and (11) are set to 50, batch size is initially set to 2000, tradeoff parameters τ_1 and τ_2 in Eq. (7) are both set to 0.5, learning rate in SGD is set to 0.01, and penalty parameters λ_1 , λ_2 , and λ_3 are set to 0.35, 0.35, and 0.3 respectively.

C. Results and Analysis

Tables III–V respectively illustrates the experimental results on three data sets. In each data set, proportion of training data is set two values: 60% and 80%. For each evaluation metric, we measure its values under two different recommendation

size 5 and 10. It can be observed from the three tables that the proposed GNN-SoR is able to perform better than baselines in most of the experiments except some a few situations. Even so, the gap with best performance is quite small. Overall, GNN-SoR performs better than other four baselines, which can be attributed to two aspects of reasons: 1) Graph neural network method is utilized in this paper to obtain a better representation of various complex relationships. 2) We model correlations of item attributes as an encoded vector and integrate it into total feature space, improving granularity of the feature space.

Then, batch size is set to 1000, 2000, 2500, 3000, 3500, and 4000, and recommendation size is set to 3, 5, 7, 8, and 10. We further conduct a set of experiments to evaluate parameter sensitivity performance of the GNN-SoR. Fig. 4 illustrates experimental results of GNN-SoR on Epinions data set under different value combinations of the two parameters. It contains three subfigures, corresponding to results of RMSE, MAE and NDCG. Similarly, Fig. 5 and 6 respectively illustrates results of GNN-SoR on Yelp data set and Flixster data set with parameters changing. These figures are color-based heatmaps, where depth of colors represents values of indexes. It can be directly observed from these figures that chromaticity difference among squares inside each subfigure is relatively small, reflecting excellent stability of GNN-SoR. This is because the GNN-SoR comprehensively

formulates feature space and is robust to different parameter settings.

V. CONCLUSION

In the upcoming 5G era, IoT will become an important part in daily life of people, especially with various social and recreational activities. This research manages to investigate application of SoR for future IoT users. In order to model fine-grained features in SoR, this article exploits correlations of item attributes, and proposes a novel framework GNN-SoR for this purpose. First, user feature space and item feature space are abstracted as two graph networks and respectively encoded via graph neural network method. Next, two encoded spaces are embedded into two latent factors of matrix factorization to complete missing rating values in user-item rating matrix. Finally, a large amount of experiments was conducted on three real-world data sets to verify efficiency and stability of the proposed GNN-SoR.
